(February 1, 2008)

The q -state Potts model with long-range interactions that decay as $1/r^\alpha$ subjected to a uniform magnetic field on d -dimensional lattices is analyzed for different values of q in the nonextensive regime $0 \leq \alpha \leq d$. We also consider the two dimensional antiferromagnetic Ising model with the same type of interactions. The mean field solution and Monte Carlo calculations for the equations of state for these models are compared. We show that, using a derived scaling which properly describes the nonextensive thermodynamic behaviour, both types of calculations show an excellent agreement in all the cases here considered, except for $\alpha = d$. These results allow us to extend to nonextensive magnetic models with $0 \leq \alpha < d$ a previous conjecture which states that the mean field theory is exact for the Ising one.

I. INTRODUCTION

Microscopic pair interactions that decay slowly with the distance r between particles appear in different physical systems. Typical examples are gravitational and Coulomb interactions, where the potential decays as $1/r$. Several other important examples can be found in condensed matter, such as dipolar (both electric and magnetic) and Ruderman-Kittel-Kasuya-Yosida (RKKY) interactions, both proportional to $1/r^3$. Effective interactions with a power law decay $1/r^\alpha$, with some exponent $\alpha \geq 0$, appear also in other related problems such as critical phenomena in highly ionic systems [1], Casimir forces between inert uncharged particles immersed in a fluid near the critical point [2] and phase segregation in model alloys [3].

It is known that some of these systems can exhibit nonextensive thermodynamic behaviour (see Refs. [4,5] and references therein). In other words, for small enough values of the ratio α/d the free energy $F = -\ln Z/\beta$, with $Z \equiv \text{Tr} \exp(-\beta H)$ (H being the Hamiltonian of the system, d the dimensionality and $\beta \equiv 1/k_B T$), grows faster than the number N of microscopic elements when $N \rightarrow \infty$, and the thermodynamic limit is not well defined.

In a recent communication [5] two of us analyzed the thermodynamics associated with the long range (LR) ferromagnetic Ising Hamiltonian

$$H = - \sum_{(i,j)} J(r_{ij}) S_i S_j \quad (S_i = \pm 1 \quad \forall i), \quad (1)$$

with

$$J(r_{ij}) = \frac{J}{r_{ij}^\alpha} \quad (J > 0; \alpha \geq 0) \quad (2)$$

where r_{ij} is the distance (in crystal units) between sites i and j , and where the sum $\sum_{(i,j)}$ runs over all distinct pairs of sites on a d -dimensional hypercubic lattice. It was shown [5] that the quantities per particle: free energy f , internal energy u , entropy s and magnetization m of a finite model of N spins behave according to Tsallis conjecture [6] for $N \gg 1$. These quantities present, in the presence of an external magnetic field h , the following asymptotic scaling behaviours:

$$u(N, T, h) \sim N^* u'(T/N^*, h/N^*) \quad (3)$$

$$f(N, T, h) \sim N^* f'(T/N^*, h/N^*) \quad (4)$$

$$s(N, T, h) \sim s'(T/N^*, h/N^*) \quad (5)$$

$$m(N, T, h) \sim m'(T/N^*, h/N^*) \quad (6)$$

for all $\alpha \geq 0$, where the functions u' , f' , s' and m' are the corresponding quantities associated with the same model but with rescaled coupling $J'(r_{ij}) = J(r_{ij})/N^*$ (these functions are independent of the system size N) and the function $N^*(\alpha)$ is defined as

$$N^*(\alpha) = \frac{1}{1 - \alpha/d} (N^{1-\alpha/d} - 1) \quad (7)$$

which behaves, for $N \rightarrow \infty$, as

$$N^*(\alpha) \sim \begin{cases} \frac{1}{\alpha/d-1} & \text{for } \alpha/d > 1 \\ \ln N & \text{for } \alpha/d = 1 \\ \frac{1}{1-\alpha/d} N^{1-\alpha/d} & \text{for } 0 \leq \alpha/d < 1 \end{cases} \quad (8)$$

For $\alpha > d$ the thermodynamic functions per site do not depend on N and the system is extensive (*i.e.*, the thermodynamic limit exists). When $0 \leq \alpha \leq d$, $N^*(\alpha)$ diverges for $N \rightarrow \infty$ and the system is non-extensive. It was also presented numerical evidence [5] that for $d = 1$ the mean field (MF) theory becomes **exact** when $0 \leq \alpha < d$. This led two of us to conjecture that the mean field theory might be exact for the nonextensive Ising model.

In this work we extend the previous analysis and present new evidences of the exactness of the MF theory for $0 \leq \alpha < d$ for the one dimensional ferromagnetic q -state LR Potts model for different values of q (including the first order phase transition predicted by MF theory for $q > 2$) and also for the two-dimensional antiferromagnetic LR Ising model in an external field. We, thus, conjecture that the MF theory might be exact for any nonextensive magnetic model excluding the borderline case $\alpha = d$, where there are probably corrections to the MF results (some previous experimental results [7] on dipolar ferromagnetic materials do not exclude this possibility).

The outline of this paper is the following. In section II we analyze the ferromagnetic q -state LR Potts model subjected to an uniform magnetic field h . First, we show that the previous analysis for the Ising model ($q = 2$) in the non-extensive region is straightforwardly extended to the generic $q > 2$ case. Then, in subsection II-A we derive the mean field solution of this model for arbitrary values of q , α and h , in particular the MF predictions for the LR bond percolation which corresponds to the $q \rightarrow 1$ and $h \rightarrow 0^+$ limit. In subsection II-B we compare the MF solution with our Monte Carlo simulation of the one-dimensional model for $h = 0$, $q = 2, 3$ and 5 and different values of α . In section III we calculate the mean field solution of the two-dimensional Ising model with competing LR antiferromagnetic and short-range ferromagnetic interactions in an external field and compare them with the Monte Carlo results of Sampaio et al [8]. Some comments and conclusions are presented in section IV.

II. POTTS MODEL WITH LONG-RANGE FERROMAGNETIC INTERACTIONS

In this section we address the LR ferromagnetic q state Potts model, *i.e.*, we consider the Hamiltonian:

$$H = -\frac{1}{2} \sum_{i,j} J(r_{ij}) \delta(\sigma_i, \sigma_j) - h \sum_i \delta(\sigma_i, 1) \quad (\sigma_i = 1, 2, \dots, q, \forall i) \quad (9)$$

where to each site, i , we associate a spin variable σ_i , which can assume q integer values; the sum $\sum_{i,j}$ runs over all distinct pairs of sites of a d -dimensional lattice of N sites ($i \neq j$); δ is the Kronecker delta function, $J(r_{ij})$ is given by Eq.(2) and h is an external magnetic field in the $\sigma = 1$ direction. The $\alpha \rightarrow \infty$ limit corresponds to the first-neighbor model. For $q = 2$ the $\alpha = 0$ limit corresponds, after a rescaling $J \rightarrow J/N$, to the Curie-Weiss model.

This model, in its plain formulation ($\alpha \rightarrow \infty$ of Eq.(9)) or in a more general one with many-body interactions, is at the heart of a complex network of relations between geometrical and/or thermal statistical models, like for example various types of percolation, vertex models, generalized resistor and diode network problems, classical spin models, etc (see [9] and references therein).

On the other hand, the Potts model with LR interactions has been much less studied. In the extensive regime $\alpha > d$ it presents a very rich thermodynamic behaviour, even in the one-dimensional case [10–12]. To the best of our knowledge, no study has been carried out for the nonextensive regime $0 \leq \alpha \leq d$.

Let us introduce the sums $\phi_i(\alpha) = \sum_{j \neq i} 1/r_{ij}^\alpha$. A sufficient condition (and believed to be necessary [13,14]) for the existence of the thermodynamic limit of this system is that

$$\phi(\alpha) = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_i \phi_i(\alpha) < \infty. \quad (10)$$

Let us now consider a d -dimensional hypercube of side $L + 1$ and $N = (L + 1)^d$, and let $i = 0$ be the central site of the hypercube. We have that

$$\phi(\alpha) = \lim_{N \rightarrow \infty} \phi_0(\alpha). \quad (11)$$

When $L \gg 1$ ($N \gg 1$) $\phi_0(\alpha)$ shows the following asymptotic behaviour [5]:

$$\phi_0(\alpha) \sim C_d(\alpha) 2^\alpha N^*(\alpha) \quad (12)$$

where $N^*(\alpha)$ is given by Eq.(7) and $C_d(\alpha)$ is a continuous function [5] of α independent of N , with $C_d(0) = 1 \forall d$. It can be proved that [5]:

$$C_1(\alpha) = \begin{cases} 1 & \text{for } 0 \leq \alpha \leq 1 \\ \frac{\alpha-1}{2^{\alpha-1}} \zeta(\alpha) & \text{for } \alpha > 1 \end{cases}. \quad (13)$$

where $\zeta(x)$ is the Riemann Zeta function. From Eqs.(7)–(12) we see that the thermodynamic limit is well defined for $\alpha > d$ (where the system presents extensive behaviour), while for $\alpha \leq d$ the system becomes non-extensive. Following the same procedure as in Ref. [5] it can be shown that the scaling behaviours (3)–(6) of the thermodynamic functions hold $\forall q \geq 2$ and $\forall \alpha \geq 0$. For $q = 2$ the system undergoes a second order phase transition at finite temperature for all $\alpha > d$ when $d \geq 2$ [15] and for $1 < \alpha \leq 2$ when $d = 1$ [16]. For $\alpha \rightarrow d^+$, the critical temperature shows the following asymptotic behaviour [15]:

$$k_B T_c \sim J \phi(\alpha) \quad (14)$$

For $d \geq 2$ and $\alpha \gg d$ (short-range case [9]) there exists a critical value q_c such that the phase transition is a second order one when $q \leq q_c(d)$ ($q_c = 4$ for $d = 2$) and a first order one for $q > q_c(d)$. For $d = 1$ and $1 < \alpha \leq 2$ Monte Carlo simulations [12] show that, for $q > 2$, there is a q -dependent threshold value $\alpha_c(q)$ such that the transition is of first order when $\alpha < \alpha_c(q)$ and of second order above it.

A. Mean field theory

In order to develop a mean field version of Hamiltonian (9) we use Mittag and Stephen [17] spin representation for the Potts model, *i.e.*, we associate to each site j a spin variable λ_j which can take the values $\lambda_j = 1, \omega, \omega^2, \dots, \omega^{q-1}$, where $\omega = e^{2\pi i/q}$ is a q th root of unity. In other words, if the site j is in the state σ then $\lambda_j = \omega^{\sigma-1}$. Then, using the property

$$q^{-1} \sum_{k=1}^q \lambda^k \lambda'^{q-k} = \delta(\lambda, \lambda') \quad (15)$$

we can rewrite the Hamiltonian (9) as:

$$H = -\frac{1}{2q} \sum_{i,j} J(r_{ij}) \sum_{l=1}^{q-1} \lambda_i^l \lambda_j^{q-l} - \frac{h}{q} \sum_i \sum_{l=1}^{q-1} \lambda_i^l - C(J, h) \quad (16)$$

where the constant term $C(J, h)$ is

$$C(J, h) = \frac{1}{2q} \sum_{i,j} J(r_{ij}) + \frac{hN}{q}. \quad (17)$$

The fraction of sites in the state σ , $n_\sigma = (1/N) \sum_i < \delta(\sigma_i - \sigma) >$, in this representation is given by:

$$n_\sigma = \frac{1}{q} \left[1 + \sum_{l=1}^{q-1} \omega^{q-l(\sigma-1)} \langle \lambda^l \rangle \right], \quad (18)$$

and the order parameter for a symmetry breaking in the $\sigma = 1$ direction is

$$m = \frac{q n_1 - 1}{q - 1}, \quad (19)$$

which can be written, using Eq.(18), as:

$$m = \frac{1}{q - 1} \sum_{l=1}^{q-1} \langle \lambda^l \rangle. \quad (20)$$

The mean field solution for this model can be easily found from the Variational Method in Statistical Mechanics [18] by using a non-interacting trial Hamiltonian H_0 given by

$$H_0 = -\eta \sum_{i=1}^N \sum_{l=1}^{q-1} \lambda_i^l \quad (21)$$

where η is the variational parameter to be found as a function of temperature. The variational free energy $\bar{F}$ is given by

$$\bar{F} = F_0 + \langle H - H_0 \rangle_0 \quad (22)$$

$$= F_0 + (\eta - \frac{h}{q}) \sum_i \sum_{l=1}^{q-1} \langle \lambda_i^l \rangle_0 - \frac{1}{2q} \sum_{i,j} J(r_{ij}) \sum_{l=1}^{q-1} \langle \lambda_i^l \lambda_j^{q-l} \rangle_0 - C(J, h) \quad (23)$$

where the free energy F_0 associated with H_0 is

$$F_0 = -\frac{N}{\beta} \ln [\exp(\beta\eta(q-1)) + (q-1) \exp(-\beta\eta)] \quad (24)$$

and $\langle \dots \rangle_0$ denotes the canonical average using the Boltzmann measure proportional to $\exp(-\beta H_0)$.

Using equality (15) one gets that

$$\langle \lambda_i \rangle_0 = \langle \lambda_i^2 \rangle_0 = \dots = \langle \lambda_i^{q-1} \rangle_0 = m_0 \quad (\forall i) \quad (25)$$

where the variational order parameter m_0 (defined by an equation similar to Eq.(20)) is related to η through:

$$m_0 = \frac{\exp(\beta\eta q) - 1}{\exp(\beta\eta q) + (q-1)} \quad (26)$$

and from the property $\lambda^{q-l} = (\lambda^l)^*$ it follows that

$$\langle \lambda_i^l \lambda_j^{q-l} \rangle_0 = m_0^2. \quad (27)$$

The minimization condition leads to

$$\eta = \frac{1}{q} [J\phi(\alpha)m_0 + h] \quad (28)$$

which, combined with Eq.(26) gives the following mean field equation for the order parameter m_0 :

$$m_0 = \frac{\exp[\beta(J\phi(\alpha)m_0 + h)] - 1}{\exp\beta[J\phi(\alpha)m_0 + h] + (q-1)}. \quad (29)$$

In the $\alpha \rightarrow \infty$ limit (short range interactions) we have $\phi(\alpha) \rightarrow z$, z being the coordination number of the lattice, and we recover, for $h = 0$, Mittag and Stephen's [17] result. For $q = 2$ the Hamiltonian (9) is equivalent to the Ising one with long range interactions, providing that $J^{Potts} = 2J^{Ising}$ and $h^{Potts} = 2h^{Ising}$. In this case Eq.(29) reduces to

$$m_0 = \tanh[\beta/2(J\phi(\alpha)m_0 + h)] \quad (30)$$

and we recover the result from Ref. [5], *i.e.*, the long range version of the Curie-Weiss equation which describes a second order phase transition for $h = 0$ at $k_B T_c / J^{Ising} \phi(\alpha) = 1$.

The variational free energy $\overline{F}$ calculated at the minimum (condition (28)) gives the following mean field free energy per site f :

$$-\beta f = \ln q + \frac{\beta J \phi(\alpha)}{2q} + \frac{1}{q} \left\{ \beta h + \frac{1}{2}(q-1)\beta J \phi(\alpha) m_0^2 + (q-1)\beta h m_0 - [1 + (q-1)m_0] \ln [1 + (q-1)m_0] - (q-1)(1-m_0) \ln (1-m_0) \right\} \quad (31)$$

where we have used Eqs. (23)–(29).

For $q \geq 3$ and $h = 0$ the transition is of first order and it is easy to verify from Eq.(31) that at the critical temperature the order parameter m jumps from zero to the value $(q-2)/(q-1)$. The critical temperature for $q \geq 3$ is given by

$$k T_c / J = \left(\frac{q-2}{q-1} \right) \frac{\phi(\alpha)}{2 \ln (q-1)}. \quad (32)$$

which recovers, in the $\alpha \rightarrow \infty$ limit, Mittag and Stephen's result [17].

In the $q \rightarrow 1$ limit, which corresponds to a bond percolation where the bond probability occupancy between any two sites i and j is p/r_{ij}^α , the order parameter *probability percolation* P_∞ (defined as the probability that a randomly chosen bond of an infinite lattice belongs to a cluster of infinite size) can be derived from [19]

$$P_\infty(p) = 1 + \lim_{\bar{h} \rightarrow 0^+} \frac{\partial}{\partial \bar{h}} \left\{ \lim_{q \rightarrow 1} \frac{\partial}{\partial q} \lim_{N \rightarrow \infty} \frac{1}{N} \ln (Z) \right\} \quad (33)$$

where $\bar{h} = \beta h$, Z is the partition function of the Potts model with coupling constants J/r_{ij}^α and p is the first neighbor bond probability given by $p = 1 - \exp(-J/k_B T)$.

One can easily show, from Eqs. (29), (31) and (33), that the probability percolation $P_\infty(p)$ is, as expected [14], exactly the $q \rightarrow 1$ and $\bar{h} \rightarrow 0^+$ limit of the order parameter m_0 , namely,

$$P_\infty = m_0(q \rightarrow 1, \bar{h} \rightarrow 0^+) = 1 - \exp\left[-\frac{J\phi(\alpha)}{k_B T} m_0(q \rightarrow 1, \bar{h} \rightarrow 0^+)\right] \quad (34)$$

or, in terms of p ,

$$P_\infty(p; \alpha) = 1 - (1-p)^{\phi(\alpha) P_\infty(p; \alpha)} \quad (35)$$

from which it follows that, due to the divergence of $\phi(\alpha)$ in the non-extensive regime, $P_\infty(0 < p \leq 1; 0 \leq \alpha \leq d) = 1$ and, hence, the critical probability $p_c(0 \leq \alpha \leq d) = 0$ in agreement with the exact result [14].

One can easily prove, from Eq.(35), that the percolation probability P_∞ of a finite system with N bonds presents an asymptotic scaling behavior similar to Eq.(6), namely

$$P_\infty(N, p) \sim P'_\infty(p^*) \quad (N \gg 1) \quad (36)$$

where p^* is the variable p calculated at $T^* = T/N^*$, namely,

$$p^* = 1 - \exp\left(-\frac{JN^*}{k_B T}\right) \quad (37)$$

and P'_∞ is the probability percolation associated with the long range bond percolation whose bond probability occupancies are p^*/r_{ij} . Using this rescaled variable p^* , the MF order parameter equation becomes, for $N \gg 1$ (see Eq.(12)):

$$P_\infty(p^*; \alpha) = 1 - (1-p^*)^{C_d(\alpha) 2^\alpha P_\infty(p^*; \alpha)} \quad (38)$$

which leads, for different values of $\alpha \in [0, d]$, to monotonously increasing distinct order parameters as p^* varies from the critical probabilities $p_c^*(\alpha, d) = 1 - \exp[-1/(C_d(\alpha) 2^\alpha)]$ to $p^* = 1$. However, if one introduces a more convenient variable, namely,

$$r^* \equiv 1 - \exp\left(-\frac{J\phi(\alpha)}{k_B T}\right) = 1 - (1-p^*)^{\frac{\phi(\alpha)}{N^*(\alpha)}} \quad (39)$$

then all these MF probability percolation curves for different values of α and d coalesce into a single curve described by the equation

$$P_\infty(r^*) = 1 - (1 - r^*)^{P_\infty(r^*)} \quad (40)$$

The critical value r_c^* where $P_\infty(r^*)$ vanishes is $r_c^* = 1 - \exp(-1) = 0.63212\dots$, which leads to the MF critical probability

$$p_c(\alpha) = 1 - \exp\left(\frac{-1}{\phi(\alpha)}\right) \quad (41)$$

Combining Eqs. (41), (12) and (8) one verifies that $p_c(\alpha \rightarrow d^+)$ vanishes asymptotically as:

$$p_c(\alpha \rightarrow d^+) \sim \frac{1}{C_d(d)2^d} \left(\frac{\alpha}{d} - 1\right) \quad (42)$$

which, in the particular case of $d = 1$, gives

$$p_c(\alpha \rightarrow 1^+, d = 1) \sim \frac{1}{2}(\alpha - 1) \quad (43)$$

Notice that the asymptotic behavior (Eq. (43)) coincides with the lower bound for $p_c(1 < \alpha \leq 2, d = 1)$ [20].

B. Monte Carlo results

We performed a Monte Carlo simulation using the heat bath algorithm on the one-dimensional Hamiltonian (9) with $h = 0$ and periodic boundary conditions for $N = 300, 600$ and 1200 , for $q = 2, 3$ and 5 , and different values of $0 \leq \alpha < 1$. We calculated the magnetization per spin (19) as a function of $T^* = T/N^*$ for different system sizes and performed a numerical extrapolation for $1/N \rightarrow 0$.

In Fig. 1 we compare the numerical results of the $q = 2$ case for $m(T^*)$ vs. $2k_B T^*/2^\alpha J$ for different values of α with the mean field solution (equation (30)). We see that all the numerical curves fall into a single one in excellent agreement with the MF prediction.

FIG. 1. Monte Carlo extrapolated results (symbols) of $m(T^*)$ vs. $2k_B T^*/(2^\alpha J)$ compared with the mean field solution (solid line) for $q = 2$

In Fig. 2 we make the same comparison for the $q = 3$ and $q = 5$ cases. The solid lines represent the MF solution given by equation (29) for $h = 0$. The dotted lines in this figure indicate the mean field prediction for the critical temperature jumps (32). Again we observe, in both cases, an excellent agreement between our simulations and MF results for $0 \leq \alpha < 1$, including the first order phase transition for $q \geq 3$.

FIG. 2. Monte Carlo extrapolated results (symbols) of $m(T^*)$ vs. $k_B T^*/(2^\alpha J)$ compared with the mean field solution (solid line) for $q = 3$ and $q = 5$.

III. ANTIFERROMAGNETIC ISING MODEL WITH LONG-RANGE INTERACTIONS

We now consider an Ising model with competing LR antiferromagnetic and short-range ferromagnetic interactions in an external field, which is described by the Hamiltonian:

$$H = -J_F \sum_{\langle i,j \rangle} S_i S_j + J \sum_{(i,j)} \frac{1}{r_{ij}^\alpha} S_i S_j - h \sum_i S_i \quad (S_i = \pm 1 \quad \forall i), \quad (44)$$

where $J > 0$, $J_F > 0$ and the sum $\sum_{\langle i,j \rangle}$ runs over nearest-neighbor sites of a d-dimensional hypercubic lattice. The above Hamiltonian reduces, for $J_F = 1$ and $J = 0.5$, to the model studied by Sampaio et al [8] through Monte Carlo simulations.

A mean field version of this model can be obtained by considering the Hamiltonian

$$H_{MF} = - \sum_i h_{eff}^i S_i \quad (45)$$

with

$$h_{eff}^i = -J \sum_{j \neq i} \frac{1}{r_{ij}^\alpha} m_j + J_F \sum_{j \text{ nni}} m_j + h, \quad (46)$$

where the sum $\sum_{j \text{ nni}}$ runs over all nearest-neighbor sites of i and

$$m_j \equiv \frac{1}{Z_{MF}} \text{Tr}_{\{S_i\}} \left\{ S_j e^{-\beta H_{MF}(\{S_i\})} \right\}, \quad (47)$$

with

$$Z_{MF} = \text{Tr}_{\{S_i\}} e^{-\beta H_{MF}(\{S_i\})}. \quad (48)$$

Now we consider the particular case of a square lattice. Dividing our lattice into two square interpenetrated sublattices A and B we can propose a solution of the form:

$$m_i = \begin{cases} m^A & \text{if } i \in A \\ m^B & \text{if } i \in B \end{cases}. \quad (49)$$

Let us introduce the functions

$$\begin{aligned} \phi^{(1)}(\alpha) &\equiv \sum_{j \in A} \frac{1}{r_{ij}^\alpha} \Big|_{i \in A} \\ \phi^{(2)}(\alpha) &\equiv \sum_{j \in B} \frac{1}{r_{ij}^\alpha} \Big|_{i \in A} \end{aligned} \quad (50)$$

with

$$\phi^{(1)}(\alpha) + \phi^{(2)}(\alpha) = \phi(\alpha)$$

It can be easily seen that

$$\begin{aligned} \phi^{(1)}(\alpha) &= 2^{-\alpha/2} \phi(\alpha) \\ \phi^{(2)}(\alpha) &= (1 - 2^{-\alpha/2}) \phi(\alpha). \end{aligned} \quad (51)$$

Then, substituting Eqs.(49) and (51) into Eq.(46) we obtain

$$h_{eff}^i = \begin{cases} -J \phi^{(1)}(\alpha) m^A - J \phi^{(2)}(\alpha) m^B + 4 J_F m^B + h & \text{if } i \in A \\ -J \phi^{(2)}(\alpha) m^A - J \phi^{(1)}(\alpha) m^B + 4 J_F m^A + h & \text{if } i \in B \end{cases} \quad (52)$$

Combining Eqs.(52), Eq.(45) and Eq.(47) we arrive, after some algebra, to the following set of MF equations for the magnetization $m = m^A + m^B$ and for the staggered magnetization $m_s = m^A - m^B$:

$$m = \frac{\sinh(2\beta [h - (J\phi(\alpha) - 4J_F)m])}{\cosh(2\beta [h - (J\phi(\alpha) - 4J_F)m]) + \cosh(2\beta [(J\phi(\alpha)(2^{1-\alpha/2} - 1) + 4J_F)m_s])} \quad (53)$$

$$m_s = \frac{-\sinh(2\beta [(J\phi(\alpha)(2^{1-\alpha/2} - 1) + 4J_F)m_s])}{\cosh(2\beta [h - (J\phi(\alpha) - 4J_F)m]) + \cosh(2\beta [(J\phi(\alpha)(2^{1-\alpha/2} - 1) + 4J_F)m_s])}. \quad (54)$$

For $h \neq 0$ it is easy to verify that the only solution of Eq.(54) and Eq.(53) is $m_s = 0$ and

$$m = \tanh[\beta (h - (J\phi(\alpha) - 4J_F)m)] \quad (55)$$

In figure 3 we compare a numerical solution of Eq.(55) with the Monte Carlo data of Sampaio et al [8] for $\alpha = 1$, $J_F = 1$, $J = 1/2$, $\beta N^*(\alpha) = (0.3)^{-1}$ and different values of N . The function $C_d(\alpha)$ for $d = 2$ was evaluated numerically. We obtained, for $\alpha = 1$, $C_2(1) = 0.8813 \pm 0.0001$. The comparison for other values of $\alpha < 2$ gave similar results.

FIG. 3. Monte Carlo simulations of Sampaio *et al.* for the magnetization m vs. a rescaled magnetic field for square lattice sizes of 32×32 (circles), 48×48 (squares) and 64×64 (triangles) for $\alpha = 1$, $J_F = 1$, $J = 1/2$ and $T^* = T/N^* = 0.3$. The solid line represents the MF solution given by Eq.(55) for $N=64 \times 64$.

A similar comparison for $\alpha = 2$ is made in figure 4 ($C_2(2) = 0.746 \pm 0.001$). The Monte Carlo data of Sampaio et al [8] do not agree very well with the MF magnetization, suggesting that corrections to the mean field result should be taken into consideration in this borderline case (where $\alpha = d$). Notice that theoretical [21] predictions and experimental results [7] obtained for the critical behavior of $d = 3$ uniaxial ferromagnets with exchange and strong dipolar interactions show that corrections to the MF behavior are needed in this $\alpha = d = 3$ case.

Summarizing this section, we verify that the Monte Carlo simulations for the equation of state of the $d = 2$ LR Ising antiferromagnet are in excellent agreement with the MF prediction when $0 \leq \alpha < 2$.

FIG. 4. Monte Carlo simulations of Sampaio *et al.* for the magnetization m vs. a rescaled magnetic field for square lattice sizes of 32×32 (circles), 48×48 (squares) and 64×64 (triangles) for $\alpha = 2$, $J_F = 1$, $J = 1/2$ and $T^* = T/N^* = 0.3$. The solid line represents the MF solution given by Eq.(55) for $N=64 \times 64$.

IV. CONCLUSIONS

We have analyzed, in this paper, two long range spin models with power law decaying interactions ($r^{-\alpha}$) under an uniform magnetic field h : (i) the q -state LR Potts ferromagnet on d -dimensional hypercubic lattices (including the $q \rightarrow 1$ and $h \rightarrow 0^+$ case of LR bond percolation) and (ii) the LR square Ising antiferromagnet with first-neighbor ferromagnetic interactions. Both models present non-extensive thermodynamic behaviors when $0 \leq \alpha \leq d$, but their thermodynamic functions become finite when conveniently scaled variables are used [6]. We have derived this scaling for $q \geq 2$ and have shown that the mean field probability percolation (i.e. the percolation order parameter) satisfies a similar scaling. The derived MF solution for the free energy of the LR Potts model led to spontaneous magnetization curves which agree very well with our Monte Carlo simulations for $d = 1$ and $q = 2, 3$ and 5 states for different values of $0 \leq \alpha < 1$. An excellent agreement occurred also between the derived MF equation of state for the above $d = 2$ antiferromagnetic LR model and the Monte Carlo simulations of Sampaio *et al* [8] for distinct values of $0 \leq \alpha < 2$. Our results strongly suggest that the **mean field theory is exact for LR non-extensive spin models with $0 \leq \alpha < d$** . This conjecture is also supported by the fact that Bergersen *et al* [22] Monte Carlo simulations of the correlation function of the LR $d=1$ Ising ferromagnet reproduce the MF result when $0 < \alpha < 1$. Since our conjecture predicts, for the $d = 1$ LR Potts ferromagnet, a first order transition for $q \geq 3$ and $0 \leq \alpha < 1$, it matches nicely with previous results [12] exhibiting first order transition for $1 < \alpha < \alpha_c(q)$.

Our results show that mean field behaviour is robust against variations of the range of interactions α within the non-extensive region, for a large class of magnetic systems. If our conjecture were true, this would have important practical implications: if you are considering systems with slow enough decaying interactions then you do not need sophisticated approximations.

It would be very interesting to extend the present analysis to more general non-extensive systems of interacting particles with long-range interactions.

V. ACKNOWLEDGMENTS

Fruitful discussions with Z. Glumac, C. Tsallis and E.M.F.Curado are acknowledged. We are grateful to Sampaio and collaborators for sending us their Monte Carlo data. This work was partially supported by grants from Consejo Nacional de Investigaciones Cientificas y Técnicas CONICET (Argentina), Consejo Provincial de Investigaciones Cientificas y
